A New Machine Learning Algorithm to Optimize A Reduced Mechanism of 2-Butanone and the Comparison with Other Algorithms

Yunpeng Wang^{1,2#}, Shibo Liu^{1#}, Jia Cheng¹, Xiao Wan^{1,2}, Wentao Feng^{1,2}, Nuo Yang^{1,2*} and Chun Zou^{1*}

2-butanone (methyl ethyl ketone) has been identified as a potential alternative fuel and fuel tracer in recent studies. In this work, a reduced mechanism containing 50 species and 190 reactions for 2-butanone is developed for the first time. The raw reduced mechanism is built in three parts using decoupling methodology, a reduced C₄-C_n sub-mechanism, a reduced C₂-C₃ sub-mechanism and a detailed H₂/CO/C₁ sub-mechanism. Subsequently, the self-adaptive differential evolution algorithm of machine learning is proposed for optimizing the reaction rates of 31 reactions in the C₄-C_n sub-mechanism to predict the ignition delay times and laminar flame speeds in constant volume bombs. The optimized reduced mechanism is validated by the ignition delay times in shock tubes and laminar flame speeds in constant volume bombs. The results of the optimized reduced mechanism are similar to those of the detailed mechanism, which show it is reliable. Moreover, the performance of the self-adaptive differential evolution algorithm is much better than the genetic algorithm and the particle swarm optimization.

1. Introduction

The burning of fossil fuels has brought severe environmental problems all over the world.^{1, 2} Considering the non-renewable of crude oil, biomass energy³ has been widely concerned as a clean and sustainable energy. Among numerous biofuel candidates,^{4,8} 2-butanone has been recently identified as a potential alternative fuel which can be used as an additive to replace ethanol in spark-ignition (SI) engines, especially for its excellent knock resistance (RON = 117).⁹ In addition, 2-butanone also has the ability to be used as tracer material in engines laser diagnostic.¹⁰ For these combustion applications, it is vital important to understand the combustion kinetics of 2-butanone.

The detailed mechanism of 2-butanone was firstly developed by Decottignies *et al.*,¹¹ who used gas chromatography to measure a methane/air flame doped with 2-butanone. Serinyel *et al.*¹² developed a detailed 2-butanone mechanism for high temperature by the measurement of the ignition delay times in shock tube. The measurement was performed at $T = 1250\text{--}1850\text{ K}$, $P = 1\text{ atm}$, $\phi = 0.5\text{--}2.0$ and fuel concentrations in the range of 1.0 % to 2.0 %.¹³ Subsequently, Badra *et al.*¹⁴ updated the Serinyel's model by new measurement of the ignition delay times at $P = 3, 6.5\text{ atm}$ and $T = 1100\text{--}1500\text{ K}$. Recently, Burke *et al.*¹⁵ developed a new 2-butanone detailed chemical kinetic model (PCFC_v1) including both high and low temperature reaction pathways, based on quantum calculations. The

model was validated against experimental data of laminar flame speeds, ignition delay times, flame speciation measurements and shock tube species-time profiles. Immediately after, Hemken *et al.*¹⁶ updated the model and proposed PCFC_v3 by adding new reaction classes of low-temperature for three butanoyl radicals and improving the branch ratios between fuel radicals. As a result, the capabilities of PCFC_v3 prediction were improved for all the experiment measurement. Although the mechanism has been validated well, it contains 387 species and 2174 reactions, which is too large to be used in a CFD (Computational Fluid Dynamics) simulation. Therefore, a reduced mechanism of 2-butanone is required for the engineering application. However, scarce works have studied the reduced mechanisms of 2-butanone.

Several methods have been proposed for the mechanism reduction. Traditional methods can be summarized as the direct reduction,^{17, 18} the directed relation graph with error propagation,^{19, 20} chemical lumping²¹ and time-scale analysis.²² Obviously, all reduction methods need to remove some species and reactions in reduced mechanism. Therefore, in order to improve the prediction accuracy of the reduced mechanism, it is necessary to adjust the rate constants of some remaining reactions. In previous work, reaction rates adjustment was usually completed by manual operation,²³ which is time-consuming and complicated. In recent years, many machine learning algorithms have been used to solve traditional problems.²⁴⁻³⁰ For mechanisms reduction, a chaos genetic algorithm (CGA) proposed by Liu *et al.*³¹ was performed for the reaction rates adjustment of reduced mechanism. Chang *et al.*³² used the Non-dominated Sorting-based Genetic Algorithm and uncertainty quantification³³ to develop an accurate reduced mechanism of n-pentanol. All of these algorithms belong to the class of evolution algorithms (EAs), in which the performance mainly depends on the combination of different generation strategies and control parameters. In order to get the most appropriate generation strategy and control parameters, it is generally needed to perform an exhaustive

Y.W. and S.L. contributed equally to this work.

search, thus, resulting in a huge amount of computational costs, especially impossible for chemical kinetics calculation. Therefore, the effective and accurate algorithms for optimization are required. The self-adaptive differential evolution algorithm (SaDE) was developed by Suganthan *et al.*,³⁴ in which both generation strategy and control parameters are adaptive adjustment during evolution. Consequently, the more suitable generation strategy and control parameters can be determined automatically at different phases of evolution process.

In the present work, the 2-butanone raw reduced mechanism containing 50 species and 190 reactions is built in three parts,³⁵ a reduced C_4 - C_n sub-mechanism, a reduced C_2 - C_3 sub-mechanism and a detailed $H_2/CO/C_1$ sub-mechanism. Subsequently, the self-adaptive differential evolution algorithm (SaDE)³⁴ is employed to optimize the reaction rate constants automatically due to its fast convergent speed and convenient operability. The ignition delay times in shock tube and laminar flame speeds are used for the validation of the reduced mechanism. Finally, the performance of SaDE algorithm is compared with genetic algorithm and particle swarm optimization.

2. Methodology

2.1 The SaDE algorithm

Fig. 1 is the data flow diagram of SaDE algorithm. The main process of SaDE, similar to other evolutionary algorithms (Eas), is aimed to find better fitness value (minimization task usually) through the iteration of the population.³⁶ The population is updated by genetic operators of mutation, crossover and selection like Darwinian evolution. The initial population was generated by coding genes in domain of definition randomly and a fitness function is set as the evolution index. Then genetic operators (mutation and crossover) will be performed on present population to generate new individuals. Subsequently, the greedy selection strategy, which means a new individual will be passed if and only if it has a better fitness value, is used to choose the final individual for next generation. Obviously, the update of the mutation strategy and control parameters self-adaptation in crossover are crucial steps of SaDE

algorithm and presented as follow:

1) The update of the mutation strategy

The mutation strategy pool for present work consist of four different strategies, *i.e.* “DE/rand/1/bin”, “DE/rand-to-best/2/bin”, “DE/rand/2/bin”, “DE/current-to-rand/1”. They are effective and famous mutation strategies in DE algorithm and the name means the generation rule of mutation individual. A mutation strategy is selected to generate new mutant individual according to the success probability learned from previous generations.³⁴ The success probability is calculated by the following equation,

$$P_{k,G} = \frac{S_{k,G}}{\sum_{k=1}^K S_{k,G}} \quad (1)$$

where

$$S_{k,G} = \frac{\sum_{g=G-LP}^{G-1} ns_{k,g}}{\sum_{g=G-LP}^{G-1} ns_{f,g} + \sum_{g=G-LP}^{G-1} nf_{k,g}} + \epsilon \quad (2)$$

($k=1, 2, \dots, K; G > LP$)

$S_{k,G}$ represents the selection probability of strategy k in generation G . LP is the learning period during evolution process. $ns_{k,g}$ is the number of individuals generated by the k strategy, which successfully passing the greedy selection within the previous LP generations. $ns_{f,g}$ is the number of failed individuals. Moreover, a small constant value $\epsilon = 0.01$ is assigned to avoid the potential null values.

2) Parameter self-adaptation

SaDE algorithm has three crucial control parameters, *i.e.* population size NP , scaling factor F , and crossover rate CR . NP is suggested no less than 5 times of genes.³⁴ F and CR are defined as followed:

$$F = N(0.5, 0.3) \quad (3)$$

$$CR = N(CRm, 0.1) \quad (4)$$

Fig. 1 The data flow diagram of SaDE algorithm.

where N means a normal distribution, CRm is the mean value of CR learned from previous LP generations and CRm is initialized as 0.5.

As demonstrated by a large number of numeric simulation experiments in,³⁷ the choice of strategy will make a great difference when solving different optimization problems. For specific problems with different characteristics, the value of CR and F has a significant impact on algorithm performance, especially for the convergence speed. By dynamically adjusting the generation strategy and control parameters, the SaDE algorithm can maintain both exploitation and exploration ability throughout the entire evolution process. According to the accurate results on various test functions³⁴ and the process of automatic regulation, it is concluded that SaDE algorithm possesses robust performance to handle optimization problems with distinct properties.

2.2 Simulation of the ignition delay time and laminar flame speed.

The ignition delay time was simulated using a zero-dimensional model with constrained volume and adiabatic boundary in Cantera 2.4.0.³⁸

The laminar flame speed was defined as the propagation speed of a steady, laminar, one-dimensional, planar, adiabatic flame.³⁹ In the present work, it was simulated using the freely-propagating, premixed flame model in Cantera 2.4.0.³⁸ The *soret* effect was accounted for and the multi-component transport model was applied. The grid ratio was set to 3, the slope 0.07 and the curve 0.14 to make sure the results are independent of the grid.

2.3 Genetic algorithm and particle swarm optimization

As mentioned above, many evolutionary algorithms (EAs) have been proposed for global optimization problem. In the present study, in order to further estimate the performance of SaDE, two famous evolutionary algorithms, genetic algorithm (GA)⁴⁰ and particle swarm optimization (PSO),⁴¹ are also conducted for 2-butanone reduced mechanism

optimization.

The typical genetic algorithm encodes the potential solutions by genes for a specific problem, and uses genetic operators to evolve these genes to get the convergent solution. Crossover rate is the crucial control parameter involved in GA. The algorithm is expected to converge fast with a small CR value and express a better exploration power with a large CR value.⁴²

Particle swarm optimization is inspired by the social species in nature, like bird, ant and fish. It is initialized with a population of random solutions and each potential solution is assigned a randomized velocity. Then, the potential solutions, named particles, will search through the domain for best solution as a fish school searching for food. Obviously, a large velocity can search solution domain fast but may miss the best solution. A small velocity, which mean a high resolution ratio, can search the solution more carefully while the rate of convergence is slow.⁴³

3. Mechanism construction

In this study, the 2-butanone raw reduced mechanism is built using the decoupling method.⁴⁴⁻⁴⁶ The main step to build a reduced mechanism is as follow:

First of all, based on the path analysis of the PCFC-v3,⁴⁷ the main reaction pathways during the combustion of 2-butanone are identified. Secondly, the isomers of large molecules or radicals are represented by only one empirical formula. For example, C_4H_7O represents for $CH_3CHCOCH_3$, $CH_2CH_2COCH_3$ and $CH_3CH_2COCH_2$, which are H-abstraction products of butanone. Only the thermal and transport properties of $CH_3CHCOCH_3$ will be adopted due to its lowest bond dissociation energy. As a result, the amount of 2-butanone H-abstraction reactions can be greatly reduced from 39 in PCFC-v3 to only 3 in the reduced mechanism. The major reaction pathway related to fuel molecule was then developed in this way and shown in Fig. 2. The

Fig. 2 Major reaction paths of reduced 2-butanone mechanism.

reduced C_4 - C_n sub-mechanism still includes the high-temperature, the low-temperature and the functional group reactions.

The reduced C_2 - C_3 mechanism is mainly taken from³² due to its good performance. Further, several reactions involving CH_3CHO and CH_3CHCO , which are important intermediates during the oxidation of 2-butanone, are integrated into the reduced C_2 - C_3 mechanism.

The detailed $H_2/CO/C_1$ sub-mechanism is taken from^{48, 49} due to its accuracy in predicting ignition delay time, JSR species measurement, flow reactor species measurement and laminar flame speed.

By combining the reduced C_4 - C_n sub-mechanism, the reduced C_2 - C_3 sub-mechanism and the detailed $H_2/CO/C_1$ sub-mechanism, a 2-butanone raw reduced mechanism with 50 species and 190 reactions is constructed.

4. Mechanism optimization

In the raw-reduced mechanism built above, the reaction rates of C_4 - C_n sub-mechanism are taken from the detailed mechanism PCFC_v3 developed by Burke *et al.*^{15, 47} The results calculated by the raw-reduced mechanism is shown in Fig. 3. It can be seen that the predicted results of raw-reduced mechanism are extremely bad among all conditions. Thus, it is necessary to tune the reaction rates of C_4 - C_n sub-mechanism to improve the performance.

4.1 Optimization setting

In the present study, the reaction rates adjustment was performed by SaDE algorithm.³⁴ Each individual represents a potential reduced mechanism of 2-butanone, and the genes in individual are reaction rates of 31 reactions in the C_4 - C_n sub-mechanism, which are listed in Table 2. The population consists of 200 individuals (no less than 5 times of genes) and the individual consists of 37 genes (2 multiplicative factors

of pre-exponential factors for the pressure-dependent reactions including R4, R21, R26, R27, R28 and R29).

The fitness function is defined as follows:

$$f(x_{i,g}) = \frac{1}{N} \sum_{n=1}^N \frac{\tau_k - \tau_0}{\tau_0} \quad (5)$$

where $f(x_{i,g})$ is the fitness value of i -th individual in the generation g ; N is the number of different experimental conditions; τ_k and τ_0 represent the simulated and experimental data, respectively.

Moreover, a terminal condition shown in Eq. (6) is introduced to improve the convergence of the optimization progress.

$$\text{Terminal condition} = \begin{cases} f_{avg,g-30} - f_{avg,g} \leq 1e-2 \\ f_{min,g-30} == f_{min,g} \end{cases} \quad (6)$$

where $f_{min,g}$ and $f_{min,g-30}$ represent the minimum fitness value of generation g and generation $g-30$, respectively. In other words, the best optimized reduced mechanism of generation g and generation $g-30$. Once the termination condition is met, the best individual of generation g is obtained as the final convergent solution, and the optimized reduced mechanism.

The main steps for optimizing raw-reduced mechanism shown in Fig. 4 can be expressed as follows:

- 1) The initial population was generated randomly by assigning value to individuals within the domain of genes.
- 2) The ignition delay times and laminar flame speeds at all conditions are calculated using Cantera code.³⁸ Then, the fitness value of each individual is calculated.
- 3) The terminal condition is judged. If yes, the final convergent solution is output, otherwise, the update of mutation strategy and

Fig. 3 Simulated results of raw-reduced mechanism. Dots represent experimental data, solid lines represent the simulated data.

parameter adaption are conducted by learning from previous *LP* generations.

4) The new generation is generated by using the operator of mutation, crossover and selection in the mating pool.

5) Steps 2) - 4) are repeated until the terminal condition is met.

4.2 Optimization object

For the optimization of the reduced mechanism, the ignition delay times measured by Serinyel *et al.*¹² at $T = 1250\text{--}1850\text{ K}$, $P = 1\text{ bar}$, $\varphi = 0.5\text{--}2.0$, Burke *et al.*¹⁵ at $T = 960\text{--}1300\text{ K}$, $P = 20\text{ and }40\text{ bar}$, $\varphi = 1.0$ and laminar flame speeds measured by Burke *et al.*¹⁵ at $T = 373\text{ K}$, $P = 1\text{ bar}$ and 5 bar , $\varphi = 0.7\text{--}1.3$, are set as the training dataset (Cases 1-8) for optimization process. Moreover, to further validate the reliability of reduced mechanism, the ignition delay times measured by Serinyel *et al.*¹² at $T = 1250\text{--}1850\text{ K}$, $P = 1\text{ bar}$, $\varphi = 1.5$ and 2.0 and laminar flame speeds measured by Serinyel *et al.*⁵⁰ at $T = 305\text{ K}$, $P = 1\text{ atm}$, $\varphi = 0.7\text{--}1.4$, are set as the test dataset (Cases 9-11) for final validation. Table 1

lists the conditions and mixture compositions, in which φ is the equivalence ratio.

4.3 Optimization results

The evolution of the fitness function is shown in Fig. 5. As can be seen from Fig. 5, the terminal condition is met at 173th generation. Thus, the best individual in 173th generation is obtained as the final convergent solution. The result of optimized reaction rates is listed in Table 2.

4.4 Evaluation indicators of mechanism

Mechanism results are evaluated through two indicators, including mean absolute error (MAE) and mean absolute percentage error (MAPE), which are defined as follows:

$$\text{MAE} = \frac{1}{n} \sum_{i=1}^n |f_i - y_i| \quad (7)$$

$$\text{MAPE} = \frac{1}{n} \sum_{i=1}^n \left| \frac{f_i - y_i}{y_i} \right| \times 100\% \quad (8)$$

Fig. 4 The implementation process of reaction rates adjustment by SaDE algorithm.

4.5 Prediction results

The comparisons between the predicted results using different mechanisms and the experimental data at Cases 1-8 are shown in Fig. 6. As can be seen, the optimized reduced mechanism predicts experimental data well for both the ignition delay times and laminar flame speeds. The optimized reduced mechanism has similar trend with detailed mechanism in all conditions. The detail errors of MAE and MAPE are shown in Table 3. The errors of optimized reduced mechanism are much less than those of the raw-reduced mechanism and even less than the detailed mechanism expect Case 6. It indicates that reduced mechanism optimized by SaDE algorithm is reliable for the prediction of ignition delay times and laminar flame speeds of 2-butanone.

4.6 Mechanism validation

Cases 9-11, which are not used for training during optimization process, are employed to validate the reduced mechanism. As shown in Fig. 7, the optimized reduced mechanism also predicts well experimental data,

Fig. 5 The evolution of the fitness function.

Fig. 6 Comparison between optimized reduced mechanism, raw reduced mechanism and detailed mechanism at Cases 1-8, experimental data are from.^{12, 15}

and has the comparable performance as the detailed mechanism. It indicates that optimized reduced mechanism has stable predictive performance. The detail errors of MAE and MAPE are listed in Table 4. Considering the both good performance of reduced mechanism for training set and test set, it can be concluded that the reduced mechanism optimized by SaDE is reasonable and believable in prediction at low-to-high temperatures and different pressures.

5. Comparison between SaDE and other evolutionary algorithms

2-butanone reduced mechanism optimization are also conducted using genetic algorithm (GA)⁵¹ and particle swarm optimization (PSO),⁴¹ respectively. The crossover rates used in GA and particle velocities used in PSO are listed in Table 5. The fitness values during the evolution process of different algorithms are shown in Fig. 8(a). Due to the large CR value of GA_2 and the small velocity of PSO_2, GA_2 and PSO_1 express a better performance than GA_1 and PSO_2, respectively. Overall, SaDE obtains a smaller fitness value and a faster convergent solution than other algorithms.

The absolute percentage errors of the prediction results of Cases 1-11 by five reduced mechanisms are shown in Fig. 8(a). Boxplot can

accurately describe the discrete distribution of data and compare the differences between different groups of data. The small box means that most data are within a small range. As can be seen in fig. 8(a), the mechanism optimized by SaDE has smaller absolute percentage errors in total, which means a more stable performance than other algorithms. Moreover, due to dynamic adjustment of generation strategy and control parameters, SaDE can avoid the time-consuming exhaustive search for the most suitable combination, which make it have better robustness for various problems with different characteristic. It is concluded that SaDE is more effective and reliable in obtaining best solution for reaction rates adjustment than other algorithms.

6. Conclusion

The 2-butanone reduced mechanism containing 50 species and 190 reactions is developed for the first time. Firstly, the raw reduced mechanism is built in three parts, *i.e.*, a reduced C_4-C_n sub-mechanism, a reduced C_2-C_3 sub-mechanism and a detailed $H_2/CO/C_1$ sub-mechanism. Secondly, the reaction rates of 31 reactions in C_4-C_n sub-mechanism are optimized by self-adaptive differential evolution algorithm to predict the ignition delay times (Cases 1-6) and flame speeds in constant volume

bombs (Cases 7-8). The optimized reduced mechanism is validated by the ignition delay times in shock tubes (Cases 9-10) and laminar flame speeds in constant volume bombs (Case 11). The results of the optimized reduced mechanism are similar to those of the detailed mechanism. Therefore, the reduced mechanism is reliable for the prediction of ignition delay times and laminar flame speeds of 2-butanone.

Moreover, the performance of self-adaptive differential evolution algorithm is much better than the genetic algorithm and the particle swarm optimization. The results demonstrate that self-adaptive differential evolution algorithm has faster convergent speed and smaller errors over a wide range of conditions. This work indicates that self-adaptive differential evolution algorithm has better robust performance and it may be a guide for future work to solve various global optimization problems in energy and fuel study.
